Applications of Power Electronics in Wind Power

Plant

Mr. Survase Sachin Shahu

Assistant Professor, Dept. of EE BMIT Institute of Technology, Solapur

Abstract: This paper reviews the power electronic applications for wind energy systems. Various wind turbine systems with different generators and power electronic converters are described, and different technical features are compared. The electrical topologies of wind farms with different wind turbines are summarized and the possible uses of power electronic converters with wind farms are shown. Finally, the possible methods of using the power electronic technology for improving wind turbine performance in power systems to meet the main grid connection requirements are discussed

Keywords: Fault ride-through, grid connection, power electronics converters, reactive power compensation, wind energy con-version, wind farms, wind turbine control.

I. INTRODUCTION

OVER the last ten years, the global wind energy capacity has increased rapidly and became the fastest developing renewable energy technology. By the end of 2006, the global wind electricity-generating capacity has increased to 74 223 MW from 59 091 MW in 2005. The early technology used in wind turbines was based on squirrel-cage induction generators (SCIGs) directly connected to the grid. Recently, the technology has developed toward variable speed. The controllability of the wind turbines becomes more and more important as the power level of the turbines increases.

Power electronic, being the technology of efficiently con- verting electric power, plays an important role in wind power systems. It is an essential part for integrating the variable- speed wind power generation units to achieve high efficiency and high performance in power systems. Even in a fixed- speed wind turbine system where wind power generators are directly connected to the grid, thyristors are used as soft- starters. The power electronic converters are used to match the characteristics of wind turbines with the requirements of grid connections, including frequency, voltage, control of active and reactive power, harmonics, etc.

This paper reviews the major applications of power electron- ics for wind power conversion systems, and it is organized as follows. Section II shows a brief review of the wind energy.

Section III discusses the issues of operating wind turbines in power systems, and Section IV presents the power quality issues and dynamic performances. Finally, in Section V, the conclusions are drawn and the future trends are illustrated.

A. Introduction of Wind Energy Conversion Systems

The main components of a wind turbine system are illustrated in Fig. 1, including a turbine rotor, a gearbox, a generator, a power electronic system, and a transformer for grid connection.

Wind turbines capture the power from wind by means of turbine blades and convert it to mechanical power. It is important to be able to control and limit the converted mechanical power during higher wind speeds. The power limitation may be done either by stall control, active stall, or pitch control whose power curves are shown in Fig. 2 [1], [2]. It can be seen that the power may be smoothly limited by rotating the blades either by pitch or active stall control while the power from a stall-controlled turbine shows a small overshoot and a lower power output for higher wind speed.

The common way to convert the low-speed, high-torque me-chanical power to electrical power is using a gearbox and a gen-erator with standard speed. The gearbox adapts the low

Volume 5, Issue 7, June 2025

The generator converts the mechanical power into electrical power, which being fed into a grid possibly through power elec-tronic converters, and a transformer with circuit breakers and electricity meters. The two most common types of electrical machines used in wind turbines are induction generators and synchronous generators.

Induction generators with cage rotor can be used in the fixed-speed wind turbines due to the damping effect. The reactive power necessary to energize the magnetic circuits must be sup-plied from the network or parallel capacitor banks at the ma-chine terminal that may have the danger of self-excitation, when connection to the network is lost. In such a case, the terminal voltage or reactive power may not be directly controlled, and the induction generators may suffer from voltage instability prob-lem, which is becoming a significant concern with large-scale wind farm penetration.

A wound rotor induction machine has a rotor with copper windings, which can be connected to an external resistor or to ac systems via power electronic systems. Such a system pro-vides a partial variable-speed operation with a small power electronic converter, and therefore increased energy capture and reduced mechanical load to the system. This type of system is an

Fig. 2. Power characteristics of fixed-speed wind turbines [2]. (a) Stall control. (b) Active stall control. (c) Pitch control.

economical way to supply reactive power and obtain variable speed for increased energy yield at wind speeds below the rated speed.

Synchronous generators are excited by an externally applied dc or by permanent magnets (PMs). There is considerable inter-est in the application of the multiple-pole synchronous genera-tors (either with PM excitation or with an electromagnet) driven by a wind-turbine rotor without a gearbox or with a low ratio gearbox. Synchronous machines powered by wind turbines may not be directly connected to the ac grid because of the require-ment for significant damping in the drive train. The use of a synchronous generator leads to the requirement for a full rated power electronic conversion system to decouple the generator from the network.

While most of the turbines are nowadays connected to the medium-voltage system, large offshore wind farms may be con-nected to the high-voltage and extra high-voltage systems. The transformer is normally located close to the wind turbines to avoid high current flowing in long low-voltage cables. The elec- trical protection system of a wind turbine system protects the wind turbine as well as secures the safe operation of the network.

B. Modern Power Electronics

Power electronics has changed rapidly during the last 30 years and the number of applications has been increasing, mainly due to the developments of the semiconductor devices and the microprocessor technology. For both cases, the performance is steadily increasing, and at the same time, the price of de-vices is continuously falling. In order to improve reliability and reduce cost, the number of components is going down by a higher level of integration. The power electronic device technology is still undergoing important progress, including some key self-commutated devices, such as insulated gate bipolar tran- sistor (IGBT), MOSFET, integrated gate commutated thyris- tor (IGCT), MOS-gate thyristors, and silicon carbide FETs. The breakdown voltage and/or current carrying capability of the components are also continuously increasing. Important re-search is going on to change the material from silicon to silicon carbide. This may dramatically increase the power density of the power converters.

Power electronic converters are constructed by semiconductor devices, driving, protection, and control circuits to perform voltage magnitude and frequency conversion and control. A converter, depending on the topology and application, may al-low both directions of power flow. There are two different types of converter systems: grid commutated and self-commutated converter systems. The grid commutated converters are mainly thyristor converters with high power capacity of 6 or 12 or even more pulses. A thyristor converter consumes inductive reactive power and it is not able to control the reactive power. Thyristor converters are mainly used for very high voltage and power applications, such as conventional HVDC systems.

Self-commutated converter systems normally adopt pulse- width-modulated (PWM) control methods; the semiconductors with turn-OFF ability, such as IGBTs, are mainly used. This type of converter may transfer both active power and reac-tive power [3], [4] in both directions (ac–dc or dc–ac). This means that the reactive power demand can be delivered by a PWM converter. The high-frequency switching of a PWM converter may produce harmonics and interharmonics, which, in general, are in the range of some kilohertz. Due to the high fre-quencies, the harmonics are relatively easier to be removed by

small-size filters. Fig. 3 shows a typical power electronic con- verter consisting of self-commutated semiconductors such as IGBTs.

Other types of circuit configurations also exist, including the multilevel converters, as shown in Fig. 4, and the matrix con-verter, as shown in Fig. 5. Especially, the multilevel converters are very interesting in such applications due to the voltage level of the converters and the decrease of the harmonics, and con-sequently, the size of the output filters. The matrix converter is technically more complicated.

II. POWER ELECTRONICS FOR INTEGRATION AND CONTROL OF WIND TURBINES

Many possible technical solutions of wind turbine electrical systems are related to power electronics, since they can improve dynamic and steady-state performances, help to control the wind turbine generator, and decouple the generator from the electrical grid [42], [46]. Some major power electronic applications are described in this section.

Fig. 6. Cage-induction-generator-based fixed-speed wind turbine with power electronic soft-starter

A. Soft-Starter for Fixed-Speed Wind Turbines

The "Danish concept" [1] of directly connecting a wind tur- bine to the grid is widely used in early wind turbine systems. The scheme consists of an SCIG, connected via a transformer to the grid and operating at an almost fixed speed. The power can be limited aerodynamically either by stall control, active stall, or pitch control. The basic configurations of the fixed-speed con- cepts are shown in Fig. 6. The advantages of wind turbines with induction generators are the simple and cheap construction, in addition that no synchronization device is required. These solutions are attractive due to cost and reliability. Some drawbacks are: 1) the wind turbine has to operate at constant speed; 2) it requires a stiff power grid to enable stable operation; and 3) it may require a more expensive mechanical construction in order to absorb high mechanical stress, since wind gusts may cause torque pulsations on the drive train. Connecting the induction generators to power system pro- duces transients that are short duration with very high inrush currents, thus causing disturbances to both the grid and high torque spikes in the drive train of wind turbines with a directly connected induction generator. Such a transient disturbs the grid and limits the acceptable number of wind turbines. The high starting currents of induction generators are usually lim-ited by a thyristor soft-starter. The current limiter or soft-starter, based on thyristor technology, typically limits the rms value of the inrush current to a level below two times of the generator rated current. The soft-starter has a limited thermal capacity and it is short circuited by a contactor, which carries the full-load current, when the connection to the grid has been completed. In addition to reduce the impact on the grid, the soft-starter also effectively dampens the torque peaks associated with the peak currents, and hence reduces the loads on the gearbox.

B. Power Electronics for Variable-Speed Wind Turbines

Variable-speed operation of a wind turbine system has many advantages. For instance, the wind turbine can increase or de-crease its speed if the wind speed and torque vary. This means less wear and tear on the tower, gearbox, and other components in the drive train. Also, variable-speed systems can increase the production of the energy and reduce the fluctuation of the power injected into the grid. In variable- speed systems, the generator is normally connected to the grid through a power electronic system.

For synchronous generators and induction generators without rotor windings, a full rated power electronic system is connected between the stator of the generator and the grid, where the total power production must be fed through the power electronic system [5], [6]. For induction generators with rotor windings, the stator of the generator is connected

Volume 5, Issue 7, June 2025

to the grid directly, and the rotor is connected to a power- electronic-controlled resistor or connected to the network through slip rings and a power electronic converter.

Fig. 7. Wound rotor induction generator with a rotor resistance converter [9].

1) Wounded Rotor Induction Generator With Rotor Resis- tance Control (Dynamic Slip Control): In this scheme, the rotor windings are connected with variable resistors. The equivalent resistance in the circuit can be adjusted by an electronic control system, as shown in Fig. 7. The higher the resistance of the rotor windings, the higher the slip is. In this way, the genera-tor speed can be varied in a limited range. Conventionally, the connection is usually done with brushes and slip rings, which is a drawback in comparison with the simple technical design of a cage rotor induction machine. It also introduces parts, which raise the maintenance requirements. This solution still needs a soft-starter [7], [8]. Both cage induction generators and rotor-resistance- controlled wounded induction generators need to op-erate at a supersynchronous speed to generate electricity. Both of them draw reactive power that might be supplied from the grid or from installed compensation equipment, such as capaci-tor banks or additional power electronic equipment. In order to keep the cost as low as possible, capacitor banks are normally used. Modern megawatt-class turbines have thyristor switched capacitors (TSCs) allowing for a more dynamic compensation. A static Var compensator (SVC) or similar technology may be needed to improve the dynamic responses of the wind farm, as will be shown in Section III.

2) Doubly Fed Induction Generator: The stator of a dou-bly fed induction generator (DFIG) is connected to the grid directly, while the rotor of the generator is connected to the grid by electronic converters through slip rings, as shown in Fig. 8. The generator can deliver energy to the grid at both supersyn- chronous and subsynchronous speeds. The slip is varied with the power flowing through the power electronic circuit. The ad- vantage is that only a part of the power production is fed through the power electronic converter. Hence, the nominal power of the power electronic converter system can be less than the nominal power of the wind turbine. In general, the nominal power of the converter may be about 30% of the wind turbine power, en-abling a rotor speed variation in the range of about $\pm 30\%$ of the nominal speed. By controlling the active power of the converter, it is possible to vary the rotational speed of the generator, and thus the speed of the rotor of the wind turbine.

Self-commutated converter systems, such as IGBT-based switching converters, are normally used for this type of system. As shown in Fig. 8, the DFIG normally uses a back-to-back con- verter, which consists of two bidirectional converters sharing a common dc link, one connected to the rotor and the other one to the grid. The power electronic converters for variable-speed generators have the ability to control both the active and reactive power delivered to the grid. This gives potential for optimizing the grid integration with respect to steady-state operation condi- tions, power quality, voltage, and angular stability.

Volume 5, Issue 7, June 2025

The reactive power to the grid from the generation unit can be controlled as zero or to a value required by the system operator within the converter rating limit. In general, the harmonics generated by the converter are in the range of some kilohertz. Thus, filters are necessary to reduce the harmonics.

The DFIG system also enables the application of special oper-ation strategies and provides the high-quality power to the grid. The acoustical noise from the wind turbines can effectively be reduced since the system can operate at a lower speed when the wind becomes quiet. The dynamic response and controllability are excellent in comparison with traditional induction generator systems. The DFIG solution needs neither a soft-starter nor a reactive power compensator.

The control system of a variable-speed wind turbine with DFIG mainly functions to:

1) adjust the power drawn from the wind turbine in order to track the optimum operation point;

2) limit the power in the case of high wind speeds;

3) regulate the reactive power exchanged between the wind turbine and the grid.

An example of an overall control scheme of a wind turbine with a doubly fed generator system is shown in Fig. 9: there are two related hierarchical control levels with different bandwidths, namely DFIG control level and wind turbine control level.

The DFIG control level performs the control of the rotor-side and the grid-side back-to-back converters. A vector control approach is adopted for the rotor controller, while two cross- coupled controllers adjust the speed and power of the system. The goals of such controllers are to track the optimum operation point, limit the power in the case of high wind speeds, and control the reactive power exchanged between the wind turbine generator and the grid. The control of the grid-side converter keeps a constant dc-link voltage while injecting the active power to the grid. Internal current loops in both converters are typically using proportional–integral (PI) controllers.

Most wind turbines use the pitch angle of the blades to limit the power when the turbine reaches the nominal power. Below the maximum power production, the wind turbine will vary the speed proportional to the wind speed and keep the pitch angle

Fig. 9. Control of wind turbine with the DFIG system [10].

nearly fixed. At a very low wind, the speed of the turbine will be fixed at the maximum allowable slip to avoid overvoltage. The wind turbine control, with slow dynamic response, supervises both the pitch system of the wind turbine as well as the active power set point of the DFIG control level. Also, some modula-tion methods have been proposed to improve the performance, such as in [47].

3) Wind Turbine Systems With Full Rated Power Electronic Converters: Cage induction generators and synchronous gen- erators may be integrated into power systems with full rated power electronic converters. The wind turbines with a full-scale power converter between the generator and grid give the added technical performance. Usually, a back-to-back voltage-source converter (VSC) is used in order to achieve full con-trol of the active and reactive power, though with synchronous generators, diode rectifiers may be used [3], [4], [11], [12], but in this case, it would be more difficult

Volume 5, Issue 7, June 2025

to fully control the whole system. Since the generator is decoupled from the grid in this system, the generator can operate at a wide vari-able frequency range for optimal operation while the generated active power will be sent to the grid through the grid-side con-verter that can be used for controlling the active and reactive power independently [3], [4], and the dynamic response may be improved.

Fig. 10 shows four possible solutions with full-scale power converters. All four solutions have almost the same controllable characteristics since the generator is decoupled from the grid by a dc link. The grid-side converter enables the system to control active and reactive power very fast. However, the negative side is a more complex system with more sensitive electronic parts. The configurations shown in Fig. 10(a) and

(b) are characterized by having a gearbox. The wind turbine sys-tem with a cage rotor induction generator and full rated power electronic converters is shown in Fig. 10(a). The synchronous generator shown in Fig. 10(b) needs a small power converter for field excitation. Multipole systems with the synchronous generator without a gear are shown in Fig. 10(c) and (d). The last solution uses PMs, which are becoming cheaper and thereby attractive.

Fig. 10. Wind turbine systems with full-scale power converters. (a) Induc-tion generator with gear. (b) Synchronous generator with gear. (c) Multipole synchronous generator. (d) Multipole PM synchronous generator.

C. Maximum Wind Power Control

As discussed previously, variable-speed wind turbines are able to operate at an optimal rotation speed as a function of the wind speed.

Impact Factor: 7.67

dP/dv

The speed of the wind turbine is used to select the stored power curve, which gives the target power to be tracked by the system. In many cases, this power curve may be substituted by a predictor or an observer of the wind speed as a function of the power and the wind-turbine speed.

1) Hill Climbing Searching (HCS) Control: This control scheme is very similar to MPPT schemes used in photovoltaic systems [17]. When the wind-turbine speed increases, the out- put power should normally increase as well, otherwise the speed should be decreased (see Fig. 15). However, this method could be ineffective for large wind turbines, since the large turbines are difficult to adjust the speed fast.

In practice, MPPT controllers may use combinations of the aforementioned three techniques [14].

dP/dv > 0

P

D. Possible Wind Farm Configurations

Large wind farms are being developed in many countries. These wind farms may present a significant power contribution to the grids, and therefore, play an important role on the power quality and the control of power systems. Consequently, high technical demands are expected to be met by these generation units, such as to perform frequency and voltage control, regula-tion of active and reactive power, quick responses under power system transient and dynamic situations, for example, it may be required to reduce the power from the nominal power to 20% power within 2 s. The power electronic technology is again an important part in both the system configurations and the con-trol of the wind farms in order to fulfill these demands. Some possible electrical configurations of wind farms are shown in Fig. 16.

A wind farm equipped with power electronic converters, as shown in Fig. 16(a), can perform both active and reactive power control and also operate the wind turbines in variable speed to Fig. 16(b) shows a wind farm with induction generators where a static synchronous compensator (STATCOM)

For long distancewind farm, HVDC may be an interesting . In an HVDC trans- mission, the low or medium ac voltage at the wind farm is converted into a high dc voltage on the transmission side and the dc power is transferred to the onshore system where the dc voltage is converted back into ac voltage, as shown in Fig. 16(d). For certain power level, an HVDC transmission system, based on VSC technology, may be used in such a system instead of the conventional thyristor-based HVDC technology. The topology may even be able to vary the speed of the wind turbines in the whole wind farm. Another possible dc transmission system con- figuration is shown in Fig. 16(c), where each wind turbine has its own power electronic converter, so it is possible to operate each wind turbine at an individual optimal speed. A compar-ison of the topologies is given in Table I. As it can be seen, the wind farms have interesting features in order to act as a power source to the grid. Some have better abilities than others. The overall considerations will include production, investment, maintenance, and reliability [48]–[50].

International Journal of Advanced Research in Science, Communication and Technology

International Open-Access, Double-Blind, Peer-Reviewed, Refereed, Multidisciplinary Online Journal

Volume 5, Issue 7, June 2025

There are also other possibilities, such as field-excited syn- chronous machines or PM synchronous generators, that can be sued in the systems, as shown in Fig. 16(c) or (d); in the case of a multiple-pole generator, the gearbox may be removed.

III. POWER QUALITY IMPROVEMENT WITH POWER ELECTRONIC DEVICES

Large-scale integration of wind turbines may have signifi-cant impacts on the power quality and power system operation. Traditionally, wind turbines are not required to participate in frequency and voltage control. However, in recent years, atten- tion has been increased on wind farm performance in power systems [18]–[21]. Consequently, some grid codes have been redefined to specify the requirements that wind turbines must meet in order to be connected to the grid. Examples of such re- quirements include the capabilities of contributing to frequency and voltage control by continuously adjusting active power and reactive power supplied to the transmission system, the power regulation rate that a wind farm must provide, flicker, harmon- ics, etc. Some of the requirements may be dealt with by power electronic technology, for example, reactive power control.

A. Reactive Power and Voltage Control

The induction-generator-based wind turbines are the con- sumer of reactive power. To minimize the power losses and increase voltage stability, these wind turbines are compensated to a level depending on the requirements of the power system.

Fig. 20. Combination of SVCs. (a) TCR with a fixed capacitor. (b) TCR with TSC.

Fig. 21. STATCOM based on VSC connected to the PCC through an inductor.

case, the switching takes place when the voltage across the thyristor is zero. Consequently, this device does not produce current harmonics. However, due to the use of switching capacitors, TSC may produce voltage transients.

The combinations between these components can pro- vide good performances of compensation. For instance, TCR can be combined with fixed capacitors or with TSC, as shown in Fig. 20. In the first case, a TCR is used in combination with a fixed capacitor bank. This solution is often used for subtransmission and distribution. The current harmonics may be eliminated by tuning the fixed capacitors as passive filters.

The second case combines TCR and TSC in one com- pensator system. Hence, a continuously variable reactive power is obtained across the entire control range plus full control of both inductive and capacitive parts of the compensator.

1) STATCOM: This system, also named SVC Light by ABB, is based on a VSC, which is used to generate reactive power. The VSC uses power electronic devices such as IGBTs, IGCTs, or gate turn-OFF thyristors (GTOs), and they can also be configured as a multilevel bidirectional converter. As shown in Fig. 21, the VSC is connected to the grid to inject or absorb reactive power through an inductor X. This system is suitable to mitigate both steady-state and transient

DOI: 10.48175/568

International Journal of Advanced Research in Science, Communication and Technology

International Open-Access, Double-Blind, Peer-Reviewed, Refereed, Multidisciplinary Online Journal

Volume 5, Issue 7, June 2025

events. Compared with SVCs, STATCOMs provide faster response, less disturbances, and better per- formance at reduced voltage levels.

From Fig. 21, if the power angle remains zero ($\delta = 0$), the active and reactive power injected to the grid by the STATCOM can be expressed as

Fig. 22. TCSC. (a) Wind farm connection. (b) Detail of the TCSC.

Consequently, the VSC acts as a reactive power generator (Q > 0, capacitive behavior) if UV > Ug , and as a reactive power absorber (Q < 0, inductive behavior) if UV < Ug . In practice, a small phase shift is used to compensate the VSC losses. The reactive power injected to the grid can be con-trolled faster than by using previous systems. The response time is limited by the switching frequency and the size of the inductor.

B. Compensation Outside a Wind Farm

In order to send the active power generated by a wind farm into the grid, the power transmission control has to be taking into account. Power oscillations and voltage collapses should be avoided. Fig. 22 shows a possible solution to avoid these drawbacks, which uses a thyristor-controlled series compensa- tion (TCSC) outside the wind farm. The TCSC changes the equivalent capacitor value by switching the parallel-connected inductor [24]. This way, a variable capacitor can be obtained and can be adjusted to increase the dynamic stability of power transmission, improve the voltage regulation and the reactive power balance, and control the power flow of the grid lines.

From Fig. 22(a), it can be seen that the active power transmit- ted from the wind farm to the grid can be expressed as follows:

$$p = \frac{u_g u_W}{\chi_L - \chi_C \sin \delta}$$
(8)

where XL is the reactance of the power line, XC is the admit-tance of the TCSC, Ug is the voltage of the grid, UW is the voltage of the wind farm, and δ is the angle between Ug and UW.

From this equation, the relationship between P and δ can be plotted, as shown in Fig. 23. It can be observed that the reactance value limits the maximum power to be transmitted, and enforces a larger power angle that can lead to instabilities

Fig. 27 shows the simulation results where the STATCOM is not in operation, but the extended rotor resistance control and turbine pitch control are applied on the wound rotor induction generator. It can be seen that the terminal voltage cannot re-store and the cage induction generator continues accelerating and loses the stability. Although the

Volume 5, Issue 7, June 2025

acceleration of the wound rotor induction generator has been limited by the extended rotor resistance control and the pitch control for a certain period, the speed of the generator will rise again after the controls have been removed. The reason is that the low voltage cannot be restored since the parallel cage induction generator loses the stability. However, part of the system may be restored if the unstable cage rotor induction generator is disconnected from the system. Fig. 28 shows the results of a successfully restoring stability case, where the STATCOM is in the operation and the rotor resistance and pitch control are also sufficiently regulated so that the system restores normal operation. The example has been shown as an important function of STATCOMs. It is also shown that the appropriate combination of various control approaches is an effective way to improve the stability.

A. Fault Ride-Through of DFIG With a Crowbar

As discussed previously, a voltage drop will spur an electro- magnetic torque reduction that leads to the acceleration of the rotor. The grid voltage decreases rapidly to a low level and will cause high current transients in the generator stator and also in the rotor, due to the magnetic coupling between the stator and rotor [37]. The high current may damage the power electronics converter connected with the rotor winding of DFIGs. There-fore, protection measures are required for DFIG wind turbines during voltage dips. A reduction in mechanical torque is desired in order to avoid overspeed. A pitch regulation, as explained before, can be used. To avoid damages in power electronics, the most common option is to block the rotor-side converter and short circuit the rotor winding by means of a so-called crow- bar [38], [39].

A crowbar is connected between the rotor of the DFIG and the rotor-side converter. The crowbar circuit may have various topologies, for example, Fig. 29 shows a crowbar consisting of a diode bridge that rectifies the rotor phase currents and a single

thyristor in series with a resistor Rcrow. The thyristor is turned on when the dc-link voltage reaches its limit value or the ro-tor current reaches its limit value. Simultaneously, the rotor of the DFIG is disconnected from the rotor-side power electronic converter and connected to the crowbar. The rotor remains con- nected to the crowbar until the main circuit breaker disconnects the stator from the network. When the grid fault is cleared, the rotor-side converter is restarted, and after synchronization, the stator of the DFIG is connected back to the network. Rotor over- current protection described before is called a passive crowbar.

The same circuit topology, as shown in Fig. 29, may be changed to an active crowbar [39] by replacing the thyristor with a fully controllable one by means of a controllable semi- conductor switch, such as an IGBT. This type of crowbar may be able to cut the short-circuit rotor current at anytime. If ei- ther the rotor current or the dc-link voltage levels exceed the limits, the IGBTs of the rotor-side converter are blocked and the active crowbar is turned on. The crowbar resistor voltage and dc-link voltage are monitored during the operation of the crowbar. When both of these voltages are low enough, the crow-bar may be turned off. After a short delay for the decay of the rotor currents, the rotor-side converter may be restarted and the reactive power may be produced to support the grid.

During normal operation, active and reactive power are con- trollable and the machine is magnetized by the rotor. However, while the rotor-side converter is disabled and bypassed, the con- trollability of active and reactive power gets lost and the magne- tization is carried out by the stator, as in an SCIG. The selection

of the Rcrow value could affect the system performance, such as reactive power controllability [40].

Doubly fed generators with rotor current control are prone to oscillations when reactive power is fed to the grid. During a voltage dip, the stability limit is further reduced. However, the generators with direct torque control (DTC) instead of vector current control seems to be reasonably stable, which could allow the rated reactive current production under low grid voltages, though voltage dips with highly unsymmetrical voltages are still difficult for DFIGs [41].

IV. CONCLUSION AND FUTURE TRENDS

This paper has reviewed the power electronic applications for wind energy systems. Various wind turbine systems with dif- ferent generators and power electronic converters are described. Different types of wind turbine systems have quite different per- formances and controllability. The electrical topologies of wind farms with different wind turbines are briefed. It has been shown that the wind farms consisting of different turbines may need different configurations for the best use of the technical merits. Furthermore, the possible methods of improving wind turbine performance in power systems to meet the main grid connection requirements have been discussed.

The wind turbine size is still increasing. Both onshore and offshore wind farms are quickly developing in a global scale. While the wind turbine market continues to be dominated by conventional gear-driven wind turbine systems, the direct drive or one-stage gear, so-called multibrid-type wind system, is at-tracting attention.

Variable-speed operation has many advantages. On the one hand, the DFIG dominates the current market for variable-speed gear-driven wind turbine systems, largely due to the fact that only the power generated in the generator rotor has to be fed through a power electronic converter system (25%– 30%). On the other hand, variable-speed wind turbines with a full-scale power converter may be more effective and less complicated to deal with grid-related problems, including the possibility for active grid support, and the potential to operate wind turbines and wind farms as power plants. Therefore, variable speed wind turbine concepts with a full-scale power converter would become more attractive.

Many power electronics configurations for wind turbine sys- tems have been actively researched, mainly the VSCs, including multiconverter configurations, are used. Compared with geared- drive wind generator systems, the main advantages of direct-drive wind generator systems are higher overall efficiency, relia-bility, and availability due to omitting the gearbox. PM machines are more attractive and superior with higher efficiency and en-ergy yield, higher reliability, and power-to-weight ratio com-pared with electricity-excited machines [42]. With synchronous generators, diode rectifiers may be used as the machine-side converters [4]. Furthermore, studies on the use of current-source converters for grid converters are reported [43], [44]. Consid- ering the performance of PMs is improving and their cost is decreasing over the recent years, combined with the fact that the cost of power electronics is decreasing, variable-speed direct- drive PM machines with a full-scale power converter have be- come more attractive for offshore wind powers.

Although the market share in the fixed-speed wind turbine concept has decreased, the market interest in SCIG-based wind turbines may increase. VSC-HVDC-based wind farms consist-ing of SCIG are robust to grid faults. Because VSC- HVDC can enhance the ability to prevent power system faults, conse-quently, the generators that are sensitive to power system faults such as SCIG can be used without the problem of ride-through power system faults.

With the increasing levels of wind turbine penetration in mod- ern power systems, grid connection issues have posed several new challenges to wind turbine design and development. Cop-ing with grid connection demands is becoming a major issue in the wind turbine industry. Recently, grid connection requirements are becoming more strict. One of the requirements is that in case of a major grid disturbance, wind turbines not only have to remain connected, but should also play an assisting role. In future, the percentage of wind energy on many grids is expected to be a significant part, thus making wind turbines as key grid players. Therefore, these machines will require a built-in capac- ity to behave

like power plants. Power electronic technologies, as the interfaces for wind turbines, also the interfaces for some energy storage systems and as flexible ac transmission systems (FACTs) devices, such as STATCOM, will play a significant role in developing new state-of-the-art solutions for the future success of various new power generation and control concepts.
