Abstract: *Electro-hydraulic servo systems (EHSSs) are nonlinear and uncertain due to their inappropriate fluid levels, air temperature, friction, and leakage. The finite-time tracking control is difficult with the use of a proportional, integral, and derivative (PID) controller, which no longer provides adequate and achievable control performance over the whole operating range. This has led to the idea of an iterative learning controller (ILC). An intelligent and memory-based learning control approach that attempts to imitate the human way of thinking. The proposed ILC has an additional learning gain, learning filter, and robustness filter to enhance the finite-time tracking performance and stability improvement. This study is focused on the design of the ILC to regulate the servo spool valve of an EHSS, which in turn controls the displacement of a hydraulic cylinder. In simulation and experimentation, vital parameters such as overshoot and settling time in the varieties of tests, the ILC has shown better results when compared to conventional PID controllers. In step input tracking at different operating points over 0-250 mm, the ILC has 40% less overshoot and settles 12-15 s faster than the PID controller. In sinewave tracking and disturbance rejection, the PID controller performs better than the ILC in integral square error and integral absolute error as the error indices are not considered as the objective function in the design of the controller. During a robustness test, the ILC rejects the uncertainty, which evidences the effectiveness of the proposed controller.*

Keywords: Closed loop control, Double acting hydraulic cylinder, Position control, Proportional integral derivative controller, Servo spool valve.

I. INTRODUCTION

An EHSS is made up of an electrically driven servo valve that regulates the hydraulic fluid fed to a cylinder. Because of their solidity, sturdiness, capability to withstand massive inertia, and stability, it is commonly employed in versatile heavy-duty applications. EHSS are used in the following application such as Autonomous tractor, Half car active suspension system, Metal bar cropping and Hydraulic press. Meanwhile, it has downsides that include external disturbances, aging, leakage and flow saturation of valve. These issues can be fixed by implementing a closed-loop controller and also the displacement precision can be increased even under harsh conditions.¹ For servo valve-based applications, many control systems have been applied, which includes model-based and non-model-based control. In the Model-based control, the efficiency, stability and accuracy are improved by using system dynamics. PID is employed in many application because of its design simplicity. Sliding Mode Controller (SMC) performs better on nonlinearity and disturbances. Zero Phase Error Tracking Controller (ZPETC) improves error tracking and response smoothness. Internal Model Controller (IMC), Model Predictive Controller (MPC), Adaptive Back-Stepping Controller (ABS) and Iterative Learning Controller (ILC) have been implemented with some standard assumption and ignorance to achieve the desired response. However, it's difficult to identify the accurate mathematical model of EHSS due to large number of model uncertainties such as external disturbances and leakages. To find the system parameters, non-

model-based control procedures are employed. It's also flexible and adaptable for modification of rules. Non-model based control strategies like Fuzzy Iterative Learning Control (FILC), the error correction in each cycle is improved. To address complex optimization issues, the PID type Genetic Algorithm (GA) is applied. For applications involving categorization and retrogression, neural networks are investigated¹³

Hybrid neural-genetic algorithm improves the precision of nonlinear systems and the Particle Swarm Optimization (PSO) reduces the computing time required for system parameter identification.¹⁴ To solve large-scale optimization problems, the Genetic Algorithm is applied to potentially facilitate the applications of the EHSS. An iterative learning mechanism is used in complex gait simulation process to maneuver Electro-hydraulic Loading System into a position trajectory that closely resembles the desired curve.

Performance of EHSS has been tested with both the learning and non-learning control schemes. The non-learning controllers may not be sufficient when there are significant environmental and plant-related uncertainties. Conventional controllers no longer offer appropriate and attainable control performance across the whole operating range, because finite-time tracking control is challenging with the usage of conventional controllers. The learning controller makes use of the error signal data from the prior cycle. It features a memory component that keeps track of the signal from the previous repetition and acts on it. Non-learning controllers are used for non-repetitive activities. It integrates few system-restrictive circumstances. Based on the complexity in system model, suitable control strategy can be implemented to improve the resistance to system uncertainty and disruptions.

To achieve a high level of precision, especially for a repeating task, ILC has been implemented. Learning from earlier iterations, ILC improves the system's performance. Learning controller offers better results by utilizing the information of earlier iteration error signals, but a non-learning controller ignores them. ILC updates the present trial input with data from prior trials, allowing performance to increase over time. ILC is best for operations that repeat the same task over a set period of time. ILC increases the system performance in manufacturing process such as Additive manufacturing, Computer numerical control machine tool, Cyclic production process and Injection molding process. ILC is applied to control the Building temperature, Chemical reactor and Current control for switched reluctance motor. ILC implemented in heavy load applications such as Electro-hydraulic Servo System, Gait simulator, Electro-hydraulic metal bar cropping and Gantry robots. ILC is successfully applied in non-repetitive practical applications. It is used to achieve high potential in the non-repetitive pick and place operation of the delta robot. ILC is implemented in mobile robot to address issues with trajectory tracking when the robot's position is unknown at the beginning of each iteration. In order to obtain accurate position and pressure tracking capabilities as well as resilience, an electro-pneumatic servo system is exposed to an ILC approach with a PID feedback loop. In wafer scanning, ILC improves the performance when the process cycle has distinct phases, where repeated disturbances are less prevalent than non-repetitive disturbances. ILC is also utilized to enhance non-repetitive performance.

Objective

- To construct an iterative learning controller for an EHSS that achieves zero overshoot and fast settling time, as well as to test and verify the system's performance.

Experimental Setup Details

Electro-Hydraulic Servo system (EHSS)

Block Diagram of Electro-Hydraulic Servo System (EHSS)

Block diagram of EHSS is shown in Fig. 1. Input block is the set point, Controller is used to regulate the displacement, and Feedback is the signal which carries the displacement information of hydraulic cylinder, Data Acquisition Card (DAQ) is employed to communicate with the programming device and hardware. Linear Variable Differential Transformer (LVDT) senses the position of hydraulic cylinder and electro hydraulic power pack stores the fluid which is used as a power medium.

Photography of Electro-hydraulic Servo System

Photograph of an EHSS is displayed in Fig. 2. DAQ is used to facilitate communication between Personal computer and EHSS. DAQ is equipped with

Figure 1: Block diagram of EHSS

Fig. 2:Photography of EHSS: 1-Personal computer (PC), 2-DAQ, 3-Hydraulic power pack, 4-Three phase fixed displacement pump, 5-Double-acting hydraulic cylinder, 6-Pressure gauge,7-LVDT, 8-Accumulator, 9-Servo spool valve

Analog to Digital Converters (ADC) and Digital to Analog Converters (DAC). LVDT senses the displacement of double-acting hydraulic cylinder and the analog signal reaches the ADC. DAC acquires the digital controller signal from controller and turns it into an analog signal that is sent to the servo spool valve. Three phase fixed displacement pump is used to generate hydraulic power for hydraulic systems. Accumulator and pressure gauge is employed to sense and store the hydraulic power respectively. The hydraulic cylinder has a stroke length of 250 mm. Displacement is monitored by an LVDT and is operated by a servo valve. The input current controls the spool-valve's displacement. The direction and speed of a piston's movement are determined by the location of the spool-valve. Software for closed loop control is built using MATLAB. The difference between the set point and obtained signal of displacement is the error signal (e). The controller uses the error signal and produces the command signal to regulate the position of hydraulic cylinder.

Functional Flow Diagram

Physical connection, fluid flow and electrical connections are shown in Fig. 3. Hydraulic powerpack is controlled by a 3-phase power source, which includes a hydraulic sump that is physically connected to a three-phase induction motor. The relief valve receives the fluid flow from the hydraulic sump via the filter and accumulator. Fluid flows from the relief valve to the hydraulic cylinder via the servo valve, with the return fluid returning to the hydraulic sump. To sense the position of the hydraulic cylinder, the LVDT is physically connected to it. An electrical connection is established between DAQ, personal computer and servo valve.

Fig. 3: Functional flow diagram of EHSS

System Dynamics

The mathematical model is derived in order to determine the system transfer function. The kinematics of an EHSS is simplified using following assumptions. i) Ignoring cylinder and valve fluid leaks. ii) Neglecting the piston-cylinder frictional force. iii) Consider that the spool position of the servo valve is critically lapped.

EHSS Parameters and Its Values

Coil resistance (R) = 20 ohm, Coil inductance (L) = 0.05 H, length of cylinder stroke (a) = 250 mm, Coefficient of discharge (C_d) = 0.7, Area gradient (w) = 0.024 m²/m, Piston's cross sectional area (A) = 0.001855 m², Pressure supply (P_s) = 3.5×10^4 Pa, Load's damping coefficient (b') = 1200 Ns/m, Density (ρ) = 839.612 Kg/m³, Mass of the load (m') = 9.5 Kg, Load-spring constant (k') = 410 N/m, Damping coefficient (b) = 540 Ns/m, Mass (m) = 0.5 Kg, Volume (V_o) = 3.1×10^{-4} m³, Spring constant (k) = 20 N/m.

Electrical Cylinder and Spool

The voltage (v) applied for an electrical actuation is described using the Current through coil (i), Inductance (L) and Spool displacement (x_v) as follows:

$$v = iR + \frac{L' \left(\frac{x_v}{a+x_v} \right) di}{dt} + \frac{iaL'}{(a+x_v)^2} \dot{x}_v \quad (1)$$

$$\frac{di}{dt} = a + \frac{x_v}{x_v L' \left(v - iR - \frac{iaL'}{(a+x_v)^2} \dot{x}_v \right)} \quad (2)$$

The magnetic force generated by the coil is used to carry the displacement in the spool plunger. The Eq.(3) relates the spool displacement, flow force and magnetic force.

$$\frac{iaL'}{(a+x_v)^2} = m\ddot{x}_v + b\dot{x}_v + kx_v + 0.43w(P_s - P_L)x_v \quad (3)$$

The spool valve's displacement is calculated using Eq. (3) as follows:

$$\ddot{x}_v = \frac{\frac{iaL'}{(a+x_v)^2} - b\dot{x}_v - kx_v - 0.43w(P_s - P_L)x_v}{m} \quad (4)$$

Double-Acting Cylinder Based on spool displacement, the fluid flow rate (QL) to the cylinder is given as

$$Q_L = C_d w x_v \sqrt{(P_s - \text{sgn} x_v P_L) / \rho} \quad (5)$$

Load

The load is driven by the pressure differential inside the cylinder.

$$AP_L = m'\ddot{X}_L + b'X_L + k'X_L'$$

$$\ddot{X}_L = \frac{AP_L - b'X_L - k'X_L'}{m'} \quad (6)$$

The load pressure (PL) and load-displacement (V (t)) are calculated as follows, where β is the bulk modulus

$$\dot{P}_L = \frac{4\beta}{v(t)}(Q_L - A\dot{X}_L); V(t) = V_o + AX_L \quad (7)$$

The system transfer function, often known as the open-loop response, is implemented in MATLAB Simulink

$$G(S) = \frac{X_v(S)}{v(s)} = \frac{40}{7.5S+1} \quad (8)$$

Controller Design

Iterative Learning Controller

Learning from prior executions is the foundation of ILC. A system that performs the same task repeatedly will function more effectively as a result. When a disturbance persists, it either rejects or adheres to a certain reference.⁷ Block diagram of Iterative Learning Controller is depicted in Fig. 4. The algorithm's performance is influenced by the robustness filter Q, learning gain K1

Fig. 4: Block diagram of iterative learning controller

and learning filter L. The convergence research uses a minimal gain under the consideration that $r_k = 0$ and all starting conditions are set as zero.

Learning Filter (L)

The error signal e_k and the feed-forward signal u_k is related. From the Fig. 4, error $e_k = r_k - y_k$

$$e_k = -y_k \quad (\because r_k = 0) \quad \dots (10)$$

Now, the output y_k

$$y_k = G(u_k + C e_k)$$

Substituting Eq. (10) we get

$$y_k = G(u_k + C(-y_k))$$

$$y_k = G u_k - G C (y_k)$$

$$y_k + G C (y_k) = G u_k$$

$$y_k (1 + G C) = G u_k$$

$$\frac{y_k}{u_k} = \frac{G}{1 + G C}$$

$$y_k = \frac{G}{1 + G C} u_k \quad \dots (11)$$

When the Eq. (11) is substituted into Eq. (10), then the error will be

$$e_k = \frac{-G}{1 + G C} u_k \quad \dots (12)$$

From Eq. (12), to find feed-forward signal U_k

$$U_k = \frac{1 + G C}{-G} \times e_k \quad \dots (13)$$

Low-pass filter $Q(s) = \omega_c / (s + \omega_c)$, where ω_c is the cut-off frequency (rad/s), is chosen as the robustness filter (Q). Similar to this, ILC feed-forward loop determines the convergence rate of the false signal using the learning gain K_L .

Learning Update Rule

From Fig. 4, the Learning update rule is derived as

$$U_{k+1} = Q \cdot u_k + K_L \cdot e_k \quad (14)$$

Error iteration $k+1$ is derived by using the Eq. (12);

$$e_{k+1} = \frac{-G}{1 + G C} u_{k+1} \quad \dots (15)$$

Error Signal for the Next Run

Subs, Eq. (14) in Eq. (15)

$$e_{k+1} = \frac{-G}{1 + G C} \left(Q u_k + L^* \frac{-G}{1 + G C} e_k \right) \quad \dots (16)$$

Subs, Eq. (16) in Eq. (15) and it becomes,

$$e_{k+1} = \left(Q + \frac{-G}{1 + G C} * L \right) e_k \quad \dots (17)$$

$$e_{k+1} = Q \left(1 - \frac{1}{Q} * \frac{G}{(1 + G C)} L \right) e_k$$

$$e_{k+1} = Q \left(1 - \frac{1}{Q} * P_s L \right) e_k \quad \dots (18)$$

where, the process complementary sensitivity;

$$P_s = \frac{G}{1 + G C}$$

Error signal transmission from each iteration is depicted in Eq. (18). Convergence occurs when $|Q (1 - P_s L)| < 1$. A replacement of the learning filter L is P_s^{-1} i.e. Responsiveness of inverted auxiliary process. Where, $P_s = G / (1 + G C)$, as a

result, the reverse inter related responsiveness P_s^{-1} is unsuitable and unstable for use as a filter with the help of the ZPETC. A discrete approximation for L is used to tackle this issue. A discrete complementary sensitivity is inputted into the technique, which reduces an unaltered stable discrete inverse complementary sensitivity. Then Eq. (18) has become,

$$e_{k+1} = Q(1 - k_i L \times P_s) e_k \quad (19)$$

If $k_i=1$ and $L = P_s^{-1}$, Eq. (19) equals to zero. Flexibility against model flaws does not exist. If $0 < k_i < 1$ is set, the convergence speed is reduced. Optimization method used in this work is used to calculate the learning gain that employs lowest tracking error as the objective function.

Magnitude and Phase Plot

Bode plot is displayed in Fig. 5. It is used to construct a robustness filter, cut-off frequency is found as 0.14 rad/s and ILC is incorporated with a proportional gain with the value of $K_p = 0.5$.

PID Controller-Design and Implementation

PID controller is employed in more than 95% of closed-loop industrial processes due to their

Fig. 5: Magnitude and Phase of Bode plot

simplicity and outstanding performance in many applications. Unlike many other modern controllers, which are far more sophisticated but sometimes deliver only minimal improvement, it can be modified by operators with little or no experience with controls.³⁴

The value of a robust controller is made evident when compared to conventional PID controllers. The transfer function is employed to determine the controller parameters. EHSS employs a PID controller to control the displacement of a double-acting hydraulic cylinder in response to an input signal. PID controller's proportional gain K_p , integral time T_i and derivative time T_d are calculated using Minimum IAE—Arrieta Orozco.³⁵

$$K_p = \frac{0.2068 + 1.1597 \left(\frac{T_m}{\tau_m} \right)^{1.0158}}{K_m}$$

$$T_i = T_m \left(-0.2228 + 1.3009 \left(\frac{T_m}{\tau_m} \right)^{0.5022} \right)$$

$$T_d = 0.3953 T_m \left(\frac{T_m}{\tau_m} \right)^{0.8469}$$

Graphical user Interface (GUI) of EHSS

MATLAB Simulink is used to create the GUI displayed in Fig. 6. Controller block intend to control the system. Input block is utilized to deliver various inputs. The analog signal from the LVDT sensor senses the displacement of hydraulic cylinder and sends the signal to analog input block and the controller sends the signal to the analog output block based on the feedback signal. Movement of the piston is indicated by the output block.

Fig. 6: Graphical user interface of EHSS

II. RESULTS AND DISCUSSION

Simulation and experimental responses of the square wave, set point tracking and servo responses were recorded to compare the performance of the ILC and PID controller.

Servo Response

The servo tracking is assessed individually for ILC and PID controller. Initially, the double-acting hydraulic cylinder is allowed to settle up to 50 sec at an intended position of 62.5 mm, 125 mm and 187.5 mm, which is 25%, 50% and 75% of the entire displacement (0–250 mm) then it undergoes a step change of $\pm 10\%$. The simulation responses are shown in Fig. 7 (a–c). The performance measures such as Maximum peak overshoot (Mp), Settling time (Ts) sec and Rise time (Tr) sec are recorded in Table 1. It's observed that ILC produces minimal overshoot of 0.2–0.6%, whereas PID controller has 1.3–3.6%. ILC has a quick settling time of 1.5 sec, but the PID controller settles at 6.2 sec. Rise time of both the controllers are almost similar, where rise time of the PID controller is 0.03 sec quicker than the ILC's. Experimental responses are shown in Fig. 8 (a–c) and their performance measures are tabulated in Table 2. ILC has a quick settling time of a minimum of 5 sec to a maximum of 23 sec lesser than PID controller. ILC has a less overshoot of 4–10%, whereas 10–45% observed in PID controller. Rise time of PID controller is 0.1–1 sec quicker than ILC. Error indices during simulation are tabulated in Table 3. PID has 10% lesser error indices (ISE and IAE) than the ILC, due to its better rise time response. Error indices during experimentation are recorded in Table 4 and it is found that PID has 11–36% of lesser error indices than the ILC.

Square Wave Tracking

The square wave tracking responses are observed with fixed amplitude of 125 with a varying pulse width of 50%, 75% and 100%. The results of square

187.5-10%	35070	834.6	38970	1023

Wave tracking responses in simulation are shown in Fig. 9 (a-c). PID has 10% overshoot meanwhile, ILC has zero overshoot at each cycle. Rise time of PID is 0.5 sec earlier than ILC and ILC settles at 5th sec whereas PID settles at 10th sec.

Fig. 9: Simulation result of square wave response at: (a) 50% of pulse width, (b) 75% of pulse width, (c) 100% of pulse width

Fig. 10: Experimental result of square wave response at: (a) 50% of pulse width, (b) 75% of pulse width, (c) 100% of pulse width

The results of square wave tracking responses at experimentation are shown in Fig. 10 (a-c). At 50% of pulse width, PID controller has failed to settle within the time period. At 75% and 100% of pulse width, PID controller response settles just before the first half cycle. Meanwhile, ILC performs more admirably than the PID controller in tracking the square wave form, it settles quickly for all the periods of the pulse width. PID has 52% overshoot but ILC has only 12%. The error indices are tabulated in Table 5. In simulation, PID suppresses ISE than ILC by 8% at 50%, 75% and 100% period of pulse width respectively. During experimentation, 3.3%, 1.6%, and 3.8% at 50%, 75%, and 100% period of pulse width is observed. In simulation, ILC produces more IAE than PID by 35%. Experimental results show the increase of 25%, 27%, and 25% at 50%, 75%, and 100% period of pulse width respectively.

Set Point Tracking

Set point tracking analysis demonstrates the controller's efficiency in the presence of changes in various set points over a period of time. The set point and time intervals of input signals are chosen randomly. The simulation result is shown in Fig. 11 a. ILC has 1–2%, where as PID has 6–11% overshoot, settling time of ILC is below 1 sec and PID controller takes 3 sec. Both the controller has similar rise time responses.

From the experimental result shown in Fig. 11 b, it's observed that ILC has 10–28% overshoot and PID has an overshoot of 30–50%. Settling time of ILC is 20–30sec, whereas the PID controller settles at 40–52 sec. Set point variation increases over the period of time. The error indices comparison is tabulated in Table 6. PID suppresses the ISE than ILC by 8% in simulation and 13% in the experimental results. ILC has a larger IAE than PID by 35% in simulation and 22% in the experimental results. Overshoot and settling time increases, when the variation of the input is higher.

To test the effectiveness of the proposed controller, SMC is compared with it. For comparison, the square wave response is simulated and it is displayed in Fig.

12. Similar responses are obtained in both controllers. To illustrate the effectiveness of ILC, error indices such as ISE and IAE are compared in Table 7. From the Table 7, it is evident that ILC has 56% lesser ISE and 23% higher IAE. From this comparison, it is deliberate that both the controllers are intelligent enough to overcome the nonlinearity and imprecision

III. CONCLUSIONS

The piston displacement of a hydraulic cylinder is controlled in this study using an ILC. The variation in time and time domain parameters in simulation and experimentation results are because of the nonlinearities and uncertainties of the system. ILC performs better than PID controllers in vital areas including notably quick settling time and lower overshoot. This exhibits the ILC's robustness and shows how the ILC technique can handle industrial hydraulic press applications that are nonlinear and unpredictable. The limitation of the proposed ILC is higher rise time and error indices as compared with PID controller, which is mainly due to model uncertainties. In future the proposed controller can be implemented in real time industrial hydraulic applications to test the feasibility of the controller.
